cutting through complexity

## Double chain-ladder and its extensions

Seminář z aktuárských věd 14 November 2014

## Introduction

## Double chain-ladder

- First moment formulation
- Parametric model and bootstrap

## External data in DCL

- BDCL method
- Zero claims, claims development inflation, triple chain-ladder

Case studies

## Reserving methods "in practice" based on triangles

- Chain-ladder
- Triangle of paid claims
- Triangle of incurred claims
- Triangle of reported claims
- Triangle of incurred counts
- Münich chain-ladder
- Triangle of paid claims + Triangle of incurred claims

## Goals

- Best estimate
- Mean square error of prediction
- VaR 99.5\%
- Full distribution
- Fit a chosen distribution to the first two moments
- Bootstrap (non-parametric / parametric)

## Aggregation of data

Triangles: aggregated data

+ Convenient presentation
- Loss of information which in some cases may lead to a poor performance

Individual claims modeling

+ No loss of information
- Usually complex models with lots of parameters
- Require large datasets (which might not be available)
- Might be computationally expensive

## Trade-off <br> Using simple model vs. Using all information

## Double chain-ladder

- „Triangular method" based on micro-level assumptions
- Using more information (two triangles + possibly additional information)
- Key question for this presentation: Does it lead necessarily to better performance?

## Double chain-ladder

## First moment formulation

Double chain-ladder
M.D. Martínez-Miranda, J. P. Nielsen, R. Verall

Astin Bulletin 2012
(published version of the paper)

## Chain-ladder

■ Using one triangle (paid / incurred / reported)
■ All sources of delay (reporting, payment) incorporated in one development pattern

## Proposed alternative

- Basic idea is to separate the sources of delay $\rightarrow$ using more than one triangle
- Triangle of incurred counts $\rightarrow$ reporting delay
- Triangle of claims paid $\rightarrow$ payment delay
- It naturally leads to frequency-severity model
- Using triangle of incurred claims as a further supplementary source of information considered in BDCL model

## Chain-ladder

- First, there was an algorithm without an underlying stochastic model

■ Underlying stochastic models added later

- Poisson model (CL is maximum-likelihood estimator)
- Mack distribution-free model
- ...

## Double chain-ladder

- First, there was an underlying exact compound Poisson model based on more detailed data
- Model to be used in practice - double chain-ladder - was originally derived as its approximation
- "Best estimate" algorithm consists of using ordinary chain-ladder twice
- "Distribution-free" formulation for the best estimate proposed later
- For VaR calculations, parametric model is recommended

New features compared to ordinary chain-ladder applied to the triangle of claims paid
■ Provides separate estimates of future cash-flows from reported claims (RBNS) and not yet reported claims (IBNR)
■ Provides a "consistent estimate of tail"

## Double chain-ladder

Formal structure and assumptions - original parametric model
$\Delta_{m}=\left\{X_{i j}:(i, j) \in I\right\}$ traingle of claims paid
$\aleph_{m}=\left\{N_{i j}:(i, j) \in I\right\}$ traingle of incurred claims counts

- Claim is not usually paid immediately after notification. This motivates the introduction of the third triangle.
$N_{i j k}{ }^{\text {paid }}$ - part of the $N_{i j}$ claims fully paid with $k$ periods delay after being reported, $k=0, \ldots, d ; d$ is max. delay
$N_{i j}{ }^{\text {paid }}$ - number of claims incurred in period $i$ and (fully) paid with $j$ periods delay

$$
N_{i j}^{\text {paid }}=N_{i j j}^{\text {paid }}+N_{i, j-1,1} 1^{\text {paid }}+N_{i, j-2,2}{ }^{\text {paid }}+\ldots+N_{i, j-\text { min }(j, d), \text { min }(j, d)}{ }^{\text {paid }}
$$

## Assumptions

- $N_{i j}$ independent, with Poisson distribution (ML estimate leads to classical CL algorithm)
- Given $N_{i j}$, the number of payments follows a multinomial distribution

$$
\left(N_{i j}{ }^{\text {paid }}, \ldots, N_{i j d} \text { paid }\right) \sim \operatorname{Multi}\left(N_{i j} ; p_{0}, \ldots, p_{d}\right)
$$

- Claim settled with one payment (or as a zero claim). Thus, if we denote $Y_{i j}(k)$ the payment for the $k$-th claim incurred in period $i$ settled with $j$ periods delay, we have

$$
X_{i j}=Y_{i j}(1)+Y_{i j}(2)+\ldots+Y_{i j}\left(N_{i j}^{\text {paiq }}\right)
$$

- $Y_{i j}(k)$ i.i.d., independent of number of claims, independent of reporting and payment delay

## Double chain-ladder

„Distribution-free" formulation
$\Delta_{m}=\left\{X_{i j}:(i, j) \in I\right\}$ traingle of claims paid
$\mathfrak{\aleph}_{m}=\left\{N_{i j}:(i, j) \in I\right\}$ traingle of incurred claims counts

- Claim is not usually paid immediately after notification. This motivates the introduction of the third triangle.
$N_{i j}{ }^{\text {paid }}$ - number of payments from $N_{i j}$ claims with / periods delay after being reported, $I=0, \ldots, m-1$;
$N_{i j}{ }^{\text {paid }}$ - number of claims incurred in period $i$ and (fully) paid with $j$ periods delay

$$
N_{i j}^{\text {paid }}=N_{i j 0}^{\text {paid }}+N_{i, j-1,1}{ }^{\text {paid }}+N_{i, j-2,2}{ }^{\text {paid }}+\ldots+N_{i, 0, j}^{\text {paid }}
$$

## Assumptions

■ $N_{i j}$ random variables with mean having a multiplicative parametrization $\mathrm{E}\left[N_{i j}\right]=\alpha_{i} \beta_{j}$ and identification $\Sigma \beta_{j}=1$ (Mack)

- The mean of the RBNS delay variables is $\mathrm{E}\left[N_{i j}\right.$ paid $\left.\mid \aleph_{m}\right]=N_{i j} \tilde{\pi}_{l}$ for each $(i, j) \in I$ and $I=0, \ldots, m-1$;
- Claim may be settled with several payments $Y_{i j}(k)$. Conditional on the number of payments, the mean of individual payment size is given by $\mathrm{E}\left[Y_{i j}(k) \mid N_{i j}\right.$ paid $]=\tilde{\mu}_{l} \gamma_{i}$. (Note that $\mathrm{E}\left[Y_{i j}(k) \mid N_{i j}\right.$ paid $]$ does not depend on $j$ - reporting delay.)

## Main differences

- Assumptions are written in terms of first moments, rather than in terms of underlying distributional assumptions
- Model allows multiple payments per claim
- Authors argued that it is rather difficult to specify a proper distribution in case that multiple payments are allowed thus this feature has a limited use when one is interested in full distribution (bootstrapping) and not only best estimate.

Basic idea: DCL estimates derived through comparison of theoretical unconditioned means of claim counts and claim payments calculated from the underlying DCL assumptions and ordinary chain-ladder.

Using the DCL assumptions, we have

$$
\begin{aligned}
\mathrm{E}\left[\sum_{k=1}^{N_{i, j-l, l}^{\text {paid }}} Y_{i, j-l, l}^{(k)} \mid \aleph_{m}\right] & =\mathrm{E}\left[\sum_{k=1}^{N_{i, j-l, l}^{\text {paid }}} \mathrm{E}\left[Y_{i, j-l, l}^{(k)} \mid \aleph_{m}, N_{i, j-l, l}^{\text {paid }}\right] \mid \aleph_{m}\right] \\
& =\mathrm{E}\left[N_{i, j-l, l}^{\text {paid }} \tilde{\mu}_{l} \gamma_{i} \mid \aleph_{m}\right]=N_{i, j-l} \tilde{\pi}_{l} \tilde{\mu}_{l} \gamma_{i}
\end{aligned}
$$

And since the aggregate payments can be written as

$$
X_{i j}=\sum_{l=0}^{j} \sum_{k=1}^{N_{i, j-l, l}^{\text {paid }}} Y_{i, j-l, l}^{(k)} \text {, for each }(i, j) \in \mathcal{I}
$$

we have ...
... for the conditional and unconditional means

$$
\mathrm{E}\left[X_{i j} \mid \aleph_{m}\right]=\sum_{l=0}^{j} N_{i, j-l} \tilde{\pi}_{l} \tilde{\mu}_{l} \gamma_{i}=\sum_{l=0}^{j} N_{i, j-l} \pi_{l} \mu \gamma_{i}
$$

$$
\mathrm{E}\left[X_{i j}\right]=\alpha_{i} \mu \gamma_{i} \sum_{l=0}^{j} \beta_{j-l} \pi_{l}
$$

where

$$
\begin{aligned}
\mu & =\sum_{l=0}^{m-1} \tilde{\pi}_{l} \tilde{\mu}_{l} \\
\pi_{l} & =\tilde{\pi}_{l} \tilde{\mu}_{l} / \mu
\end{aligned}
$$

- It is possible to use both conditional and unconditional mean to estimate „RBNS" part
- It is possible to use unconditional mean to estimate „IBNR" part
- Parameters $\alpha_{i j} \beta_{j}$ can be estimated using ordinary chain-ladder applied on the triangle of claim counts

■ It remains to estimate $\mu_{,} \gamma_{i}$ and $\pi_{l}$.

Ordinary chain-ladder assumptions applied on the triangle of claims paid say there exist parameters $\widetilde{\boldsymbol{\alpha}}_{i}, \widetilde{\boldsymbol{\beta}}_{j}$, so that it is satisfied

$$
\mathrm{E}\left[X_{i j}\right]=\widetilde{\alpha}_{i} \widetilde{\beta}_{j}
$$

A direct comparison with the previous formula

$$
\mathrm{E}\left[X_{i j}\right]=\alpha_{i} \mu \gamma_{i} \sum_{l=0}^{j} \beta_{j-l} \pi_{l}
$$

leads to a natural identification

$$
\begin{aligned}
\alpha_{i} \mu \gamma_{i} & =\widetilde{\alpha}_{i} \\
\sum_{l=0}^{j} \beta_{j-l} \pi_{l} & =\widetilde{\beta}_{j}
\end{aligned}
$$

■ Parameters $\alpha_{i}, \beta_{j}$ and $\widetilde{\alpha}_{i}, \widetilde{\beta}_{j}$ can be estimated using the ordinary chain-ladder method on the triangles of incurred counts and claims paid. Let us denote these estimates by $\widehat{\boldsymbol{\alpha}}_{i}, \widehat{\boldsymbol{\beta}}_{j}$ and $\widehat{\widetilde{\boldsymbol{\alpha}}}_{i}, \widehat{\widetilde{\boldsymbol{\beta}}}_{j}$.
■ They can be used for estimates of $\mu, \gamma_{i}$ and $\pi_{l}$ in the following way.

The second identification formula

$$
\sum_{l=0}^{j} \beta_{j-l} \pi_{l}=\widetilde{\beta}_{j}
$$

allows to estimate $\pi_{l}$ using estimates of the other two coefficients, $\hat{\beta}_{j}$ and $\hat{\tilde{\beta}}_{j}$. For the estimate of $\pi_{l}$, one then needs to solve a linear system

$$
\left(\begin{array}{c}
\widehat{\tilde{\beta}}_{0} \\
\vdots \\
\vdots \\
\widehat{\tilde{\beta}}_{m-1}
\end{array}\right)=\left(\begin{array}{cccc}
\hat{\beta}_{0} & 0 & \cdots & 0 \\
\hat{\beta}_{1} & \hat{\beta}_{0} & \ddots & 0 \\
\vdots & \ddots & \ddots & 0 \\
\hat{\beta}_{m-1} & \cdots & \hat{\beta}_{1} & \hat{\beta}_{0}
\end{array}\right)\left(\begin{array}{c}
\pi_{0} \\
\vdots \\
\vdots \\
\pi_{m-1}
\end{array}\right)
$$

Let us denote the solutions by $\hat{\pi}_{l}$.

Other parameters can be estimated using the first identification formula

$$
\alpha_{i} \mu \gamma_{i}=\widetilde{\alpha}_{i}
$$

by estimates of the other two coefficients, $\hat{\alpha}_{i}$ and $\hat{\tilde{\alpha}}_{i}$, got from ordinary chain-ladder and using the formula

$$
\widehat{\gamma}_{i}=\frac{\widehat{\widetilde{\alpha}}_{i}}{\widehat{\alpha}_{i} \widehat{\mu}}
$$

since it is natural to put $\gamma_{1}=1$ and estimate

$$
\widehat{\mu}=\frac{\widehat{\widetilde{\alpha}}_{1}}{\widehat{\alpha}_{1}}
$$

$\checkmark$ Estimates of all parameters complete

For the conditional and unconditional means, we have

$$
\mathrm{E}\left[X_{i j} \mid \aleph_{m}\right]=\sum_{l=0}^{j} N_{i, j-l} \tilde{\pi}_{l} \tilde{\mu}_{l} \gamma_{i}=\sum_{l=0}^{j} N_{i, j-l} \pi_{l} \mu \gamma_{i}
$$

$$
\mathrm{E}\left[X_{i j}\right]=\alpha_{i} \mu \gamma_{i} \sum_{l=0}^{j} \beta_{j-l} \pi_{l}
$$

where

$$
\begin{aligned}
& \mu=\sum_{l=0}^{m-1} \tilde{\pi}_{l} \tilde{\mu}_{l} \\
& \pi_{l}=\tilde{\pi}_{l} \tilde{\mu}_{l} / \mu
\end{aligned}
$$

- It is possible to use both conditional and unconditional mean to estimate the „RBNS" part
- It is possible to use unconditional mean to estimate the „IBNR" part

Two possible estimates for „RBNS" component and one for „IBNR" component:

$$
\begin{aligned}
\widehat{X}_{i j}^{r b n s(1)} & =\sum_{l=i-m+j}^{j} N_{i, j-l} \hat{\pi}_{l} \hat{\mu} \hat{\gamma}_{i} \\
\widehat{X}_{i j}^{r b n s(2)} & =\sum_{l=i-m+j}^{j} \widehat{N}_{i, j-l} \hat{\pi}_{l} \hat{\mu}^{\gamma_{i}} \\
\widehat{X}_{i j}^{i b n r} & =\sum_{l=0}^{i-m+j-1} \widehat{N}_{i, j-l} \hat{\pi}_{l} \hat{\mu}_{i} \hat{\gamma}_{i}
\end{aligned}
$$

where

$$
\hat{N}_{i j}=\hat{\alpha}_{i} \hat{\beta}_{j}
$$

Two possible estimates for „RBNS" component and one for „IBNR" component:

$$
\begin{aligned}
\widehat{X}_{i j}^{r b n s(1)} & =\sum_{l=i-m+j}^{j} N_{i, j-l} \hat{\pi}_{l} \hat{\mu} \hat{\gamma}_{i} \\
\widehat{X}_{i j}^{r b n s(2)} & =\sum_{l=i-m+j}^{j} \widehat{N}_{i, j-l} \hat{\pi}_{l} \hat{\mu}^{2} \hat{\gamma}_{i} \\
\widehat{X}_{i j}^{i b n r} & =\sum_{l=0}^{i-m+j-1} \widehat{N}_{i, j-l} \hat{\pi}_{l} \hat{\mu}^{2} \hat{\gamma}_{i}
\end{aligned}
$$

where

$$
\hat{N}_{i j}=\hat{\alpha}_{i} \hat{\beta}_{j}
$$

It is also possible to include an estimate of tail

$$
\widehat{R}^{\text {tail }}=\sum_{(i, j) \in \mathcal{J}_{2} \cup \mathcal{J}_{3}} \sum_{l=0}^{\min (j, d)} \widehat{N}_{i, j-l} \hat{\pi}_{l} \hat{\mu}^{\gamma_{i}}
$$

- The credibility of the estimate relies heavily on the fact whether „the full run-off" is observed in the first accident year

## Two main features in which DCL differs from ordinary CL

- Estimate considers not only the lower triangle but also the tail
- Two possible estimates for the „RBNS" part
- The first one feels more natural as it uses the true observed value
- Using the second one and ignoring the tail, we arrive exactly to the ordinary chain-ladder estimate
- Both estimates will be close to each other if there is little difference between $N_{i j}$ and $\widehat{N}_{i j}$

## Distribution-free assumptions

■ Underlying model does not rely on specific distributional assumptions

## Main disadvantage

■ First moment formulation suitable only for the best estimate

- Proposed solution: fit a parametric model and use a parametric bootstrapping

## Case study

First part

Best estimate in "distribution-free" DCL

## Data

- 33 triangles

■ Based on data observed in different lines of business (MTPL, TPL, Casco, Property, Travel, Accident, Sickness, Property)

- 6 long tailed
- 27 short tailed
- No salvages \& subrogations

Analysis based on the ordinary chain-ladder as a benchmark

- Concerning the best estimate, there are, in fact, only two sources of difference:
- Using observed rather than "averaged" number of claims in the RBNS part
- Estimate of tail

We did not apply any smoothing of development factors in the underlying chain-ladder estimates

- No strictly standardized methodology $\rightarrow$ leading to arbitrary choices and possible misinterpretations

Case study: first part
Best estimate in "distribution-free" DCL (cont'd)

## Results

- In majority of examined triangles (30 of 33), little difference between ordinary CL and DCL predictions
- Basic descriptive indicators (diff of total reserves by DCL and CL / total reserve by CL applied on paid triangle)

| DCL without tail | Diff in \% |
| :---: | :---: |
| Min | $-5,7 \%$ |
| Max | $+2,1 \%$ |
| Average | $-0,6 \%$ |
| StDev | $+1,3 \%$ |
| DCL with tail | Diff in $\%$ |
| Min | $-5,5 \%$ |
| Max | $+12,1 \%$ |
| Average | $+0,5 \%$ |
| StDev | $+3,3 \%$ |

Case study: first part
Best estimate in "distribution-free" DCL (cont'd)

## Results

- Tail relevant in long tailed lines of business (MTPL, TPL)

■ For short lines of business, the influence of tail usually negligble

| DCL without tail, <br> short tailed LoBs | Diff in \% |
| :---: | :---: |
| Min | $-5,7 \%$ |
| Max | $+2,1 \%$ |
| Average | $-0,7 \%$ |
| StDev | $+1,4 \%$ |
| DCL with tail, | Diff in \% |
| short tailed LoBs | $-5,5 \%$ |
| Min | $+2,1 \%$ |
| Max | $-0,7 \%$ |
| Average | $+1,4 \%$ |
| StDev |  |

## Results

- Tail relevant in long tailed lines of business (MTPL, TPL)

■ For short lines of business, the influence of tail usually negligble

| DCL without tail, <br> long tailed LoBs | Diff in \% |
| :---: | :---: |
| Min | $-1,1 \%$ |
| Max | $+0,1 \%$ |
| Average | $-0,5 \%$ |
| StDev | $+0,4 \%$ |
| DCL with tail, | Diff in \% |
| Iong tailed LoBs | $+0,2 \%$ |
| Min | $+12,1 \%$ |
| Max | $+5,2 \%$ |
| Average | $+4,5 \%$ |
| StDev |  |

## RBNS estimate

- Comparison of DCL estimate / case-by-case estimate
- Total
- Last accident period

Without several exceptions (Casco), it differs a lot in both cases - by tens of percent. Possible reasons:

- Run-off (case-by-case reserves are not BE)
- In majority of cases, the DCL shows an indication of over/underreserving consistently with the run-off test

■ RBNS in older periods: wrong tail, low number of still opened claims

- Real world $=$ best estimate
- Assumptions of DCL:
- Average claim can differ in accident years but not in reporting periods (usually not satisfied)
- One payment pattern cannot capture differences in accident years

## Backtesting

- Test proposed by authors of the method
- Cut-off last 1-4 diagonals and compare the accuracy of CL / DCL predictions
- Potential weakness: better fit may be simply a coincidence

## Results

- DCL very slightly more precise ( 1.0 \% on average, quite likely statistically insignificant)
- Test on 4 cut-off diagonals:
- 19 of 30 triangles: difference less than $1 \%$ on total reserves
- 25 of 30 triangles: difference less than $3 \%$ on total reserves
- 27 of 30 triangles: difference less than $5 \%$ on total reserves
- 28 of 30 triangles: difference less than $10 \%$ on total reserves
- 2 remaining triangles: difference of $10.4 \%$ and $22.9 \%$ (DCL being more precise in both cases)
$\rightarrow$ The accuracy of ordinary CL and DCL in the „naive" approach is very similar
$\rightarrow$ If one method is (in)accurate, so is the other

Case study: first part
Diagnostics (cont'd)

## Charts

- Payment delay (factors $\pi_{l}$ )
- Example of stable, short-tailed triangle

## Case study: first part

Diagnostics (cont'd)

## Charts

- Payment delay (factors $\pi_{l}$ )
- Example of unstable and long-tailed triangle

Case study: first part
Diagnostics (cont'd)

## Charts

- Inflation (factors $\gamma_{i}$ )
- Chart on the left side: well-behaved development, irregularity in the most recent years
- Chart on the right side: either extreme volatility in average claim or the model does not fit well

Other

- Average claim amounts
- Check on market data
- Number of claims
- Does it correspond to the market share?
- Checks common in ordinary chain-ladder
- Predicted claim ratios in accident years
- Claims development pattern
- Outliers
$-\ldots$

Except the reporting delay and payment delay patterns, other values can be compared to the market Reporting delay and the payment delay can be inspected in detail through detailed data

## Example of the parametric model

Parametric bootstrap

## Double chain-ladder

Formal structure and assumptions - parametric model
$\Delta_{m}=\left\{X_{i j}:(i, j) \in \Lambda\right.$ traingle of claims paid
$\aleph_{m}=\left\{N_{i j}:(i, j) \in\right\}$ traingle of incurred claims counts

- Claim is not usually paid immediately after notification. This motivates the introduction of the third triangle.
$N_{i j k}{ }^{\text {paid }}$ - part of the $N_{i j}$ claims fully paid with $k$ periods delay after being reported, $k=0, \ldots, d, d \leq m-1$
$N_{i j}^{\text {paid }}$ - number of claims incurred in period $i$ and (fully) paid with $j$ periods delay

$$
N_{i j}^{\text {paid }}=N_{i j 0}^{\text {paid }}+N_{i, j-1,1}{ }^{\text {paid }}+N_{i, j-2,2}{ }^{\text {paid }}+\ldots+N_{i, j-m i n(j, d), \text { min }(j, \text { d })}{ }^{\text {paid }}
$$

## Assumptions

- $N_{i j}$ independent, with Poisson distribution (ML estimate leads to classical CL algorithm)
- Given $N_{i j}$, the numbers of payments follow a multinomial distribution

$$
\left(N_{i j}{ }^{\text {paid }}, \ldots, N_{i j d}^{\text {paid }}\right) \sim \operatorname{Multi}\left(N_{i j} ; p_{0}, \ldots, p_{d}\right)
$$

- Claim settled with one payment. Thus, if we denote $Y_{i j}(k)$ the payment for the $k$-th claim incurred in period $i$ settled with $j$ periods delay, we have

$$
X_{i j}=Y_{i j}(1)+Y_{i j}(2)+\ldots+Y_{i j}\left(N_{i j}^{\text {paic }}\right)
$$

- $Y_{i j}(k)$ are mutually independent, with distributions $f_{i}$, mean $\mu_{i}=\mu \gamma_{i}$ and variance $\sigma_{i}^{2}=\sigma^{2} \gamma_{i}^{2}$
- $Y_{i j}(k)$ independent of number of claims, independent of reporting and payment delay

## Double chain-ladder

Formal structure and assumptions - parametric model (cont'd)

Individual claims distribution (severity distribution) may be chosen

- One possible choice is gamma distribution with the mean $\mu_{i}$ and the variance $\sigma_{i}^{2}$

■ Thus it has the shape parameter $\lambda_{i}=\mu_{i}^{2} / \sigma_{i}^{2}$ and the scale parameter $\kappa_{i}=\sigma_{i}^{2} / \mu_{i}$.

- Given the count $N_{i j}^{\text {paid }}$, the aggregate claims $X_{i j}$ are again gamma distributed with shape $N_{i j}{ }^{\text {paid }} \lambda_{i}$ and scale $\kappa_{i}$ (sum of identically gamma distributed random variables is again gamma distributed random variable)
$\Rightarrow$ Need to estimate $\sigma_{i}^{2}$
$\rightarrow$ Need to estimate $p_{l}$, since the original estimate of parameters $\pi_{l}$ may lead both to negative values and values which does not sum up to 1

From the estimate of $\pi_{l}$, one can estimate $p_{l}$ by several ways, authors suggested two very simple methods

- Maximal delay $d$ is estimated by summing the number of succesive estimates of $\pi_{l}$ until a number greater or equal to one is achieved. Then $d$ is equal to the count of summands and it is put

$$
\begin{aligned}
\widehat{p}_{l} & =\widehat{\pi}_{l}, l=0, \ldots, d-1 \\
\widehat{p}_{d} & =1-\sum_{l=0}^{d-1} \widehat{p}_{l}
\end{aligned}
$$

- Nullify negative $\pi_{l}$ coefficients and then rescale them so that their sum would be equal to 1 .
- In practice:
- There should be (!) either way little difference between $\pi_{l}$ and $p_{l}$;
- It is advised to use the option which would less modify the best estimate.

Adjustments of the payment pattern can change the predictions quite a bit

- These were the results with general coefficients $\pi_{l}$

| DCL without tail | Diff in \% |
| :---: | :---: |
| Min | $-5,7 \%$ |
| Max | $+2,1 \%$ |
| Average | $-0,6 \%$ |
| StDev | $+1,3 \%$ |
| DCL with tail | Diff in $\%$ |
| Min | $-5,5 \%$ |
| Max | $+12,1 \%$ |
| Average | $+0,5 \%$ |
| StDev | $+3,3 \%$ |

Adjustments of the payment pattern can change the predictions quite a bit

- This is how they change for the first adjustment ("cut-off")

| DCL without tail | Diff in $\%$ |
| :---: | :---: |
| Min | $-5,7 \% \rightarrow-24,8 \%$ |
| Max | $+2,1 \% \rightarrow+22,8 \%$ |
| Average | $-0,6 \% \rightarrow-2,0 \%$ |
| StDev | $+1,3 \% \rightarrow+7,3 \%$ |
| DCL with tail | Diff in $\%$ |
| Min | $-5,5 \% \rightarrow-23,4 \%$ |
| Max | $+12,1 \% \rightarrow+22,8 \%$ |
| Average | $+0,5 \% \rightarrow-1,2 \%$ |
| StDev | $+3,3 \% \rightarrow+7,1 \%$ |

Adjustments of the payment pattern can change the predictions quite a bit

- This is how they change for the second adjustment ("nullifying and rescaling")

| DCL without tail | Diff in $\%$ |
| :---: | :---: |
| Min | $-5,7 \% \rightarrow-1,1 \%$ |
| Max | $+2,1 \% \rightarrow+51,5 \%$ |
| Average | $-0,6 \% \rightarrow+6,2 \%$ |
| StDev | $+1,3 \% \rightarrow+10,4 \%$ |
| DCL with tail | Diff in $\%$ |
| Min | $-5,5 \% \rightarrow-1,1 \%$ |
| Max | $+12,1 \% \rightarrow+51,5 \%$ |
| Average | $+0,5 \% \rightarrow+7,4 \%$ |
| StDev | $+3,3 \% \rightarrow+10,5 \%$ |

## Double chain-ladder

Influence on the results of case studies (cont'd)

## Differences between adjustments

- Can be both small / large
- For this case, the difference between best estimates using "cut-off" and "nullify and rescale" adjustments was over 10 \%
- All three patterns coincide in the first two periods. Green and blue line almost coincides also for the following periods.

Double chain-ladder
Influence on the results of case studies (cont'd)

## Differences between adjustments

- In the previous slide, the adjustment by "nullifying and rescaling" was minor but this might not be the case every time

For bootstrap, we also need the estimates of the variance parameters.

Estimate of variance parameters is based on the fact, that the claims amounts follow (approximately) over-dispersed Poisson model

- See Appendix A for details

$$
\begin{aligned}
\mathrm{V}\left[X_{i j} \mid \aleph_{m}\right] & \approx \frac{\sigma_{i}^{2}+\mu_{i}^{2}}{\mu_{i}} \mathrm{E}\left[X_{i j} \mid \aleph_{m}\right] \\
& =\gamma_{i} \frac{\sigma^{2}+\mu^{2}}{\mu} \mathrm{E}\left[X_{i j} \mid \aleph_{m}\right] \\
& =\varphi_{i} \mathrm{E}\left[X_{i j} \mid \aleph_{m}\right]
\end{aligned}
$$

where

$$
\begin{aligned}
\varphi_{i} & =\gamma_{i} \varphi \\
\varphi & =\frac{\sigma^{2}+\mu^{2}}{\mu}
\end{aligned}
$$

We can estimate the over-dispersion parameter using the over-dispersion (Pearson $X^{2}$ ) statistics

$$
\widehat{\varphi}=\frac{1}{n-(d+1)} \sum_{i, j \in \mathcal{I}} \frac{\left(X_{i j}-\widehat{X}_{i j}^{D C L}\right)^{2}}{\widehat{X}_{i j}^{D C L} \widehat{\gamma}_{i}}
$$

Where

$$
n=m(m+1) / 2
$$

and

$$
\widehat{X}_{i j}^{D C L}=\sum_{l=0}^{\min (j, d)} N_{i, j-l} \hat{p}_{l} \hat{\mu} \hat{\gamma}_{i}
$$

The variance factors are then estimated by

$$
\begin{gathered}
\widehat{\sigma}^{2}=\widehat{\mu} \widehat{\varphi}-\widehat{\mu}^{2} \\
\widehat{\sigma}_{i}^{2}=\widehat{\sigma}^{2} \widehat{\gamma}_{i}^{2}
\end{gathered}
$$

## RBNS part of the reserve

Reported counts: left-top triangle /

- The actual values $N_{I}$ are observed

Aggregated claims $X_{i j}$ arising from (already) reported claims (triangles I $u J_{1} u J_{2}$, only I is observed)

- Constructed sequentially:
- Given reported counts $N_{i j}$, number of payments $N_{i j k}{ }^{\text {paid }}$ follows the multinomial distribution

$$
\left(N_{i j 0}{ }^{\text {paid }}, \ldots, N_{i j d}{ }^{\text {paid }}\right) \sim \operatorname{Multi}\left(N_{i j} ; p_{0}, \ldots, p_{d}\right)
$$

- The paid counts $N_{i j}^{\text {paid }}$ are defined by

$$
N_{i j}{ }^{\text {paid }}=N_{i j 0}{ }^{\text {paid }}+N_{i, j-1,1}{ }^{\text {paid }}+N_{i, j-2,2}{ }^{\text {paid }}+\ldots+N_{i, j-\min (j, d), \text { min }(j, d)^{\text {paid }}}
$$

- Individual claims distribution (severity distribution) chosen as gamma distribution

Double chain-ladder
Parametric bootstrapping - underlying distributions (IBNR part)

## IBNR part of the reserve

Incurred but not yet reported counts: right-bottom triangle $J_{1}$

- Poisson distribution $N_{J I}$

Aggregated claims $X_{i j}$ arising from incurred but not yet reported claims (triangles $J_{1} \cup J_{2} u J_{3}$ )

- Constructed analogically to the previous "RBNS case", given the prediction of claims counts $N_{J I}$

## Double chain-ladder

Bootstrapping - process variance + parameter estimation error

## Process variance (stochastic error) only

- Simulation of unknown parts of the triangles (bottom-right + tail) from estimated parameters
- RBNS part: simulate claims payments using the previous construction
- IBNR part: simulate number of claims in the triangle $J_{1}$ and, based on this, simulate claims payments as in the RBNS part
- In these simulations, parameters of the underlying distributions are fixed (except the simulated claims counts in the IBNR part)

## Process variance and parameter estimation errors

- Estimated parameters used for a simulation of new „left-top" triangle(s)
- RBNS part: only paid triangle (as I use observed values in triangle of counts for the estimate of the RBNS)
- IBNR part: both triangle of payments and triangle of counts
- From these new triangles, "bootstrapped" parameters are estimated

■ From "bootstrapped" parameters, the unknown parts of triangles are simulated

Proposed algorithm for the bootstrapping procedure - RBNS part
Estimate of process variance only - do only steps 1, 4 and 5 (using parameters estimated in the step 1).

## 1. Parameters estimation

- Apply the procedure described for the best estimate to obtain estimates for $p, \mu, \sigma^{2}, \lambda, \kappa$

2. Bootstrapping the data

- Keep the same counts N , but bootstrap the aggregate payments $\mathrm{X}^{*}$ as follows
- Simulate the delay (construct $N_{i j}{ }^{\text {paid }}$ from given $N_{i j}$ using the multinomial distribution estimated in the step 1)
- Simulate the aggregate payments using gamma distribution with shape parameter $N_{i j}{ }^{\text {paid }} \lambda$ and scale parameter $\kappa$

3. Bootstrapping the parameters

- From the bootstrap data ( $\mathrm{N}, \mathrm{X}^{*}$ ) generated at step 2 obtain new estimates for $p^{*}, \mu^{*}, \sigma^{2 *}, \lambda^{*}, \kappa^{*}$

4. Bootstrapping the RBNS prediction

- Simulate the delay as in the step 2
- Simulate the aggregate payments as in the step 2
- Get the bootstrapped RBNS prediction

5. Monte Carlo approximation

- Repeat steps 2-4 B times and get the empirical bootstrap distribution of the RBNS part of the reserve

## Double chain-ladder

## Bootstrapping - algorithm schema (RBNS part)

Algorithm RBNS - Bootstrapping taking into account the uncertainty parameters

## Proposed algorithm for the bootstrapping procedure - IBNR part

## 1. Parameters and distribution estimation

- Apply the procedure described for the best estimate to obtain estimates for $p, \mu, \sigma^{2}, \lambda, \kappa$ and use the chain-ladder to estimate future incurred claims counts $(\omega)$.

## 2. Bootstrapping the data

- Get new counts $N^{*}$ and aggregate payments $X^{*}$ as follows
- Simulate new counts $N^{*}$ (in the upper-left triangle) using Poisson distribution (with parameters estimated by the chain-ladder method in the step 1)
- Using $N^{*}$, simulate $X^{*}$ as in the second step of the RBNS procedure

3. Bootstrapping the parameters

- From the bootstrap data ( $N^{*}, X^{*}$ ) generated at step 2 obtain new estimates for $p^{*}, \mu^{*}, \sigma^{2 *}, \lambda^{*}, \kappa^{*}$ and use the chainladder to get bootstrapped future incurred claims counts.

## 4. Bootstrapping the RBNS prediction

■ Simulate the delay for $N_{i j}{ }^{*}$ using $p^{*}$, i.e. construct $N_{i j}{ }^{\text {paid", IBNR }}$ analogously to the step 2 of the "RBNS" procedure

- Simulate the aggregate payments as in the step 2 and get the bootstrapped IBNR prediction (an. "RBNS" procedure)

## 5. Monte Carlo approximation

- Repeat steps 2-4 B times and get the empirical bootstrap distribution of the IBNR part of the reserve

## Double chain-ladder

## Bootstrapping - algorithm schema (IBNR part)

Algorithm IBNR - Bootstrapping taking into account the uncertainty parameters

## Case study

 Second partDCL bootstrapping

Case study: second part DCL bootstrapping

## Data

- Same as in the first part. Tested on 30 triangles with small differences between CL and DCL best estimates.

## Comparison with

- Mack's estimate of mean squared error of prediction (MSEP)
- Chain-ladder "two-stage" bootstrap method by Verall and England (1999) and England (2001)
- Resampling residuals
- Simulating payments from ODP distribution

Results: coefficient of variation (cumulative figures)

| \| MSEP^(1/2) / BE | | < 5\% | < 10\% | < 15\% | < 20\% | < 25\% |
| :---: | :---: | :---: | :---: | :---: | :---: |
| CL bootstrap | 1 | 9 | 15 | 21 | 23 |
| Mack analytic estimate | 0 | 6 | 11 | 17 | 20 |
| DCL, "cut-off" | 0 | 3 | 9 | 12 | 17 |
| DCL, "nullifying and rescaling" | 0 | 12 | 17 | 21 | 24 |
| \| MSEP^(1/2) / BE | | < 25\% | < 30\% | < 40\% | < 50\% | $\geq 50 \%$ |
| CL bootstrap | 23 | 26 | 27 | 28 | 2 |
| Mack analytic estimate | 20 | 25 | 26 | 26 | 4 |
| DCL, "cut-off" | 17 | 18 | 19 | 20 | 10 |
| DCL, "nullifying and rescaling" | 24 | 24 | 24 | 25 | 5 |

Results: coefficient of variation, differences to CL bootstrap (incremental figures)

- Number of triangles where the difference (in \% of best estimate) between CL bootstrap (by England) and considered alternatives falls in the range:

| MSEP^(1/2), differences <br> to CL bootstrap | $<\mathbf{5 \%}$ | $\mathbf{5 \% - 1 0 \%}$ | $\mathbf{1 0 \% - 2 5 \%}$ | $\mathbf{2 5 \% - 5 0 \%}$ | $\mathbf{\geq 5 0 \%}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Mack analytic estimate | 16 | 9 | 3 | 1 | 1 |
| DCL, "cut-off" | 11 | 3 | 5 | 3 | 8 |
| DCL, "nullifying and rescaling" | 21 | 3 | 1 | 1 | 4 |

Results: VaR 95\% and VaR 99\% (incremental figures)

- Unlike for best estimates, the results of bootstrap can differ quite significantly
- Number of triangles where the difference (in \% of best estimate) between CL and DCL bootstraps falls in the range:

| VaR 95\%, differences <br> to CL bootstrap | $<\mathbf{5 \%}$ | $\mathbf{5 \% - 1 0 \%}$ | $\mathbf{1 0 \% - 2 5 \%}$ | $\mathbf{2 5 \% - 5 0 \%}$ | $\geq \mathbf{5 0 \%}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| DCL, "cut-off" | 12 | 2 | 6 | 0 | 10 |
| DCL, "nullifying and rescaling" | 16 | 6 | 2 | 1 | 5 |
| VaR 99\%, differences <br> to CL bootstrap | $<5 \%$ | $\mathbf{5 \% - 1 0 \%}$ | $\mathbf{1 0 \% - 2 5 \%}$ | $\mathbf{2 5 \% - 5 0 \%}$ | $\geq \mathbf{5 0 \%}$ |
| DCL, "cut-off" | 10 | 3 | 0 | 5 | 12 |
| DCL, "nullifying and rescaling" | 13 | 7 | 4 | 0 | 6 |

■ Adjustments in DCL payment delay parameters ("cut-off" or "nullifying and rescaling") led in several cases to unrealistic estimates, but such an estimate was rarely seen for both adjusting methods at once

## Results: VaR 95\% and VaR 99\% (incremental figures)

■ Adjustments in DCL payment delay parameters ("cut-off" or "nullifying and rescaling") led in several cases to unrealistic estimates, but such an estimate was rarely seen for both adjusting methods at once

- If we take the estimate "closer" to the chain-ladder bootstrap

| VaR 95\%, diff. | $<\mathbf{5 \%}$ | $\mathbf{5 \% - 1 0 \%}$ | $\mathbf{1 0 \% - 2 5 \%}$ | $\mathbf{2 5 \% - 5 0 \%}$ | $\mathbf{\geq 5 0 \%}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| DCL, "cut-off" | 12 | 2 | 6 | 0 | 10 |
| DCL, "nullifying and rescaling" | 16 | 6 | 2 | 1 | 5 |
| DCL, choosing closer est. | 17 | 7 | 2 | 0 | 4 |

| VaR 99\% | $<\mathbf{5 \%}$ | $\mathbf{5 \% - 1 0 \%}$ | $\mathbf{1 0 \% - 2 5 \%}$ | $\mathbf{2 5 \% - 5 0 \%}$ | $\geq \mathbf{5 0 \%}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| DCL, "cut-off" | 10 | 3 | 0 | 5 | 12 |
| DCL, "nullifying and rescaling" | 13 | 7 | 4 | 0 | 6 |
| DCL, choosing closer est. | 16 | 6 | 3 | 1 | 4 |

## External data in DCL method

Accident year inflation parameter

DCL and Bornhuetter-Ferguson
M.D.Martínez-Miranda, J. P. Nielsen, R. Verrall

April 2011 (preliminary), NAAJ 2013

## Main difference

- Estimate of the inflation parameter using triangle of incurred claims

The name "Bornhuetter-Ferguson" is chosen simply because a (distant) resemblance

- Classical BF method replace the chain-ladder estimate of ultimate claim by a prior estimate derived differently

$$
\begin{aligned}
& {\widehat{\widehat{C_{i, J}}}}^{\mathrm{BF}}=C_{i, I-i}+\left(1-\widehat{\beta}_{I-i}^{(\mathrm{CL})}\right) \widehat{\mu}_{i} \\
& {\widehat{C_{i, J}}}^{\mathrm{CL}}=C_{i, I-i}+\left(1-\widehat{\beta}_{I-i}^{(\mathrm{CL})}\right){\widehat{C_{i, J}}}_{\mathrm{CL}}
\end{aligned}
$$

- The proposed adjustment to the DCL method is similar in the sense, that an inflation parameter derived by the DCL algorithm replaces by the inflation parameter derived differently (but not completely deliberately, in fact, the DCL algorithm is simply not applied on the paid triangle but on the incurred triangle instead)

Inflation parameter is estimated using the identification formula

$$
\alpha_{i} \mu \gamma_{i}=\widetilde{\alpha}_{i}
$$

where alpha coefficients are estimated using the chain-ladder method on triangles of incurred counts (without tilde " $\sim$ ") and claims paid (with tilde " $\sim$ "). Then we can estimate

$$
\widehat{\gamma}_{i}=\frac{\widehat{\widetilde{\alpha}}_{i}}{\widehat{\alpha}_{i} \widehat{\mu}}
$$

and since the model is over-parametrized, this is solved by putting $\gamma_{1}=1$ and

$$
\widehat{\mu}=\frac{\widehat{\widetilde{\alpha}}_{1}}{\widehat{\alpha}_{1}}
$$

BDCL
Proposed adjustment compared to DCL

## Two step procedure:

Parameter estimation
■ Estimate all parameters ( $\boldsymbol{\pi}, \mathbf{p}, \mu, \gamma, \sigma$ ) using the DCL procedure.
■ Note that $\gamma$ parameters estimated here using the paid triangles are implicitly used for the estimate of $\sigma$ !

## Proposed adjustment

- Repeat the estimation using the incurred triangle instead of the paid one
- Replace only the inflation parameters $\gamma$

## Personal accident data "from major insurer" - 19 accident years

## KPMG

## BDCL

## Best estimates differ dramatically

- Which result is more reliable?

## Back-testing

- Compare predictions based on triangles with deleted last $1,2,3, \ldots$ diagonals with reality
- Authors did the back-testing on quarterly triangles

Results of the Back-Test to Evaluate of the Discrepancy between Estimates and Actual Numbers

| $m_{c}$ | DCL | BDCL | Rerr |
| :---: | :---: | :---: | :---: |
| 78 | $221,665.5$ | $99,071.9$ | 0.4469 |
| 77 | $210,708.1$ | $98,297.5$ | 0.4665 |
| 76 | $233,875.4$ | $84,232.2$ | 0.3602 |
| 75 | $317,434.6$ | $77,075.6$ | 0.2428 |
| 74 | $283,276.9$ | $87,542.4$ | 0.3090 |

Note: The second and third columns show the (square root) mean squared error of the estimates by DCL and BDCL, respectively. The discrepancies have been evaluated on the last $m-m_{c}$ diagonals in the original quarterly paid triangle. The last column shows the relative error defined as the ratio of the BDCL and the DCL errors.

## Case study

Third part

BDCL: best estimate and bootstrapping

Case study: third part
BDCL best estimate and bootstrapping

## Data

- Same as in the first part.

Similar statistics as in the first two parts for DCL

Best estimate: BDCL, "moment" type best estimates

- Table below summarizes both DCL and BDCL compared to ordinary CL (applied on paid triangle)
- There are significant differences $\boldsymbol{\rightarrow}$ they are related to the differences between the prediction of claims reserves from paid and incurred triangles

| Without tail | DCL to CL | BDCL to CL |
| :---: | :---: | :---: |
| Min | $-5,7 \%$ | $-54,1 \%$ |
| Max | $+2,1 \%$ | $+20,2 \%$ |
| Average | $-0,6 \%$ | $-4,1 \%$ |
| StDev | $+1,3 \%$ | $+13,3 \%$ |

| With tail | DCL to CL | BDCL to CL |
| :---: | :---: | :---: |
| Min | $-5,5 \%$ | $-53,9 \%$ |
| Max | $+12,1 \%$ | $+23,0 \%$ |
| Average | $+0,5 \%$ | $-3,0 \%$ |
| StDev | $+3,3 \%$ | $+13,0 \%$ |

## Case study: third part

Rel. differences of other estimates to the ordinary chain-ladder applied on paid triangles for 30 tested triangles (moment type variants of DCL and BDCL)

Case study: third part
BDCL best estimate - parametric models

Adjustments of the payment pattern

- First type ("cut-off")

| DCL without tail | Diff in $\%$ |
| :---: | :---: |
| Min | $-54,1 \% \rightarrow-58,1 \%$ |
| Max | $+20,2 \% \rightarrow+24,9 \%$ |
| Average | $-4,1 \% \rightarrow-5,4 \%$ |
| StDev | $+13,3 \% \rightarrow+16,1 \%$ |
| DCL with tail | Diff in $\%$ |
| Min | $-53,9 \% \rightarrow-58,1 \%$ |
| Max | $+23,0 \% \rightarrow+24,9 \%$ |
| Average | $-3,0 \% \rightarrow-4,7 \%$ |
| StDev | $+13,0 \% \rightarrow+15,8 \%$ |

Case study: third part
BDCL best estimate - parametric models

Adjustments of the payment pattern

- Second type ("nullifying and rescaling")

| DCL without tail | Diff in $\%$ |
| :---: | :---: |
| Min | $-54,1 \% \rightarrow-38,0 \%$ |
| Max | $+20,2 \% \rightarrow+53,9 \%$ |
| Average | $-4,1 \% \rightarrow+2,8 \%$ |
| StDev | $+13,3 \% \rightarrow+17,1 \%$ |
| DCL with tail | Diff in $\%$ |
| Min | $-53,9 \% \rightarrow-37,8 \%$ |
| Max | $+23,0 \% \rightarrow+53,9 \%$ |
| Average | $-3,0 \% \rightarrow+3,9 \%$ |
| StDev | $+13,0 \% \rightarrow+16,6 \%$ |

## External data in DCL method

## Zero claims

Claims development inflation

Double Chain Ladder, Claims Development Inflation and Zero Claims
M.D. Martínez-Miranda, J. P. Nielsen,
R. Verrall, M. Wüthrich

August 2013

## Adding prior knowledge

Adding prior knowledge to the (B)DCL

- About future zero claims
- About future severity development inflation

The aim is to improve the bootstrap, not the best estimate

## Adding prior knowledge

## Parametric model structure

$\Delta_{m}=\left(X_{i j}: 1 \leq i+j \leq m\right)$ triangle of claims paid
$\aleph_{m}=\left(N_{i j}: 1 \leq i+j \leq m\right)$ triangle of incurred claims
$N_{i j}$ paid - number of claims payment originating from the reported $N_{i j}$ claims which are paid with / periods delay after being reported, $I=0, \ldots, m-1$;
$Y_{i j}(k)$ - individual payments which arise from $N_{i j}{ }^{\text {paid. }}$. For total payments Xij we have

## Assumptions

$$
X_{i j}=\sum_{l=0}^{j} \sum_{k=1}^{N_{i, j-l, l}^{\text {paid }}} Y_{i, j-l, l}^{(k)}
$$

- $N_{i j}$ independent, with Poisson distribution (as in Mack chain-ladder)
- Given $N_{i j}$, the numbers of payments follow a multinomial distribution

$$
\left(N_{i j}{ }^{\text {paid }}, \ldots, N_{i j d}{ }^{\text {paid }}\right) \sim \operatorname{Multi}\left(N_{i j} ; p_{0}, \ldots, p_{a}\right)
$$

■ $Y_{i j}(k)$ i.i.d., mutually independent, independent of $N_{i j}$, having a mixed type distribution

- With probability $Q_{i}$ of being zero claim
- Conditionally, if not being a zero claim, $Y_{i j}(k)$ has a distribution with mean $\mu_{i j}$ and variance $\sigma_{i j}{ }^{2}$ where
- $\mu_{i j}=\mu \gamma_{i} \delta_{j}$
- $\sigma_{i j}^{2}=\sigma^{2} \gamma_{i}^{2} \delta_{i}^{2}$
- $\delta_{j}$ and $\gamma_{i}$ can be interpreted as an inflation in the payment and accident periods

## Adding prior knowledge

Incorporating prior knowledge on claims development inflation

Treating only the claims development inflation is easy (i.e. we assume no zero claims, $Q_{i}=0$ )

- We simply adjust the paid triangle with values

$$
\tilde{X}_{i j}=X_{i j} / \delta_{j}
$$

- Then the adjusted paid triangle together with the triangle of counts follow the same model assumptions with $\delta_{j}=1$ which means that the usual DCL algorithm can be applied.
- The DCL algorithm provides the prediction

$$
\tilde{X}_{i j}^{D C L}
$$

- And, finally, this prediction is transformed back by

$$
\widetilde{X}_{i j}^{D C L P}=\delta_{j} \widetilde{X}_{i j}^{D C L}
$$

Adding prior knowledge
Incorporating prior knowledge on claims development inflation and zero claims

Incorporation of both zero claims and claims development inflation is based on a similar adjustment

$$
\tilde{X}_{i j}=X_{i j} /\left[\delta_{j}\left(1-Q_{i}\right)\right]
$$

but the rest is more complicated.

We illustrate how the bootstrap procedure changes in this case.

RBNS part of the algorithm

1. From the triangles of counts and payments adjusted using the formula on the previous slide, derive "DCL" parameters: $p_{p}, \gamma_{j}, \mu, \sigma^{2}$.
2. Generate new triangle of payments as follows

- Simulate the payments $N_{i j}$ paid ${ }^{*}$ from a multinomial distribution $\left(N_{i j} ; p_{0}, \ldots, p_{m-1}\right)$
- Simulate the number of nonzero payments $N_{i j} j^{\text {paid }}$ using a binomial distribution with the size $\Sigma N_{i j}$ paid $^{*}$ and the probability $\left(1-Q_{i}\right)$
- Simulate the payments $X_{i j}{ }^{*}$ from gamma distribution with the shape parameter $N_{i j}{ }^{\text {paid }} \gamma_{i} \gamma_{i} / \sigma_{i}$ and the scale parameter $\sigma_{i}^{2} / \gamma_{i} \mu$, where $\sigma_{i}^{2}=\left(1-Q_{i}\right) \sigma^{2}-Q_{i} \mu$

3. Estimate "DCL" parameters again based on the original triangle of claims counts and simulated triangle of payments which is again adjusted for zero claims: $X_{i j}{ }^{* a d j}=X_{i j}{ }^{*} /\left(1-Q_{i}\right)$.
4. Simulate the RBNS cash-flows using the step 2 with parameters obtained in the step 3. Adjust the simulated payments by a multiplication with the inflation factor $\delta_{j}$.
5. Repeat the steps 2-4 B times (Monte Carlo).

IBNR part of the algorithm is modified in a similar way.

## "Triple" chain-ladder

Statistical modelling and forecasting of outstanding liabilities in non-life insurance
M.D. Martínez-Miranda, J. P. Nielsen,
M. Wüthrich

June 2012

## Triple chain-ladder

Main differences

## Main differences to double chain-ladder

- The third triangle, number of payments, is assumed to be available
- It is used to model more detailed payment pattern
- In particular, parametric model can deal with more than one payment per claim
- More detailed model vs. more complex
- More general assumptions, namely concerning inflation
- Calendar year inflation is not modeled. It is assumed to be extracted up front, if necessary

## Triple chain-ladder

Model structure
$\Delta_{m}=\left\{X_{i j}:(i, j) \in I\right\}$ triangle of claims paid
$\mathfrak{\aleph}_{m}=\left\{N_{i j}:(i, j) \in I\right\}$ triangle of incurred claims counts
$R_{m}=\left\{N_{i j}^{\text {paid }}:(i, j) \in I\right\}$ triangle of number of payments
$N_{i j}$ paid - number of payments from $N_{i j}$ claims with / periods delay after being reported, $I=0, \ldots, m-1$;
$N_{i j}{ }^{\text {paid }}$ - number of claims incurred in period $i$ and (fully) paid with $j$ periods delay

$$
N_{i j}^{\text {paid }}=N_{i j 0}{ }^{\text {paid }}+N_{i, j-1,1}{ }^{\text {paid }}+N_{i, j-2,2}{ }^{\text {paid }}+\ldots+N_{i, 0, j}^{\text {paid }}
$$

$Y_{i j}(k)$ - individual claim payments, $k=1, \ldots, N_{i j}$ paid. Hence,

$$
X_{i j}=\sum_{l=0}^{j} X_{i j l}, \quad X_{i j l}=\sum_{k=1}^{N_{i, j-l, l}^{p a i d}} Y_{i, j-l, l}(k)
$$

## Assumptions

- All random variables in different accident years are independent

■ $N_{i j}$ are independent and Poisson distributed with $\mathrm{E}\left[N_{i j}\right]=\vartheta_{i} \beta_{j}$ and identification $\vartheta_{1}=1$

- Claims payments $X_{i j l}$ are, conditionally given number of $N_{i j}, \ldots, N_{i, m-1}$, independent (in $\Lambda$ ) and compound Poisson distributed with
$-N_{i j} f^{\text {paid }} \mid\left\{N_{i 0}, \ldots, N_{i, m-1}\right\} \sim \operatorname{Poi}\left(N_{i j} \pi_{i}\right)$ with given parameter $\pi_{l}>0$;
$-Y_{i j}(k) \mid\left\{N_{i j}, \ldots, N_{i, m-1}\right\}$ are i.i.d. (in $k$ ) with $\mathrm{E}\left[Y_{i j}(k)\right]=v_{i} \mu_{j j}, \mathrm{E}\left[Y_{i j}(k)^{2}\right]=v_{i}^{2} s_{j j}{ }^{2}$ with given parameters $v_{i}, \mu_{j} \mid, s_{j l}>0, v_{1}=1$

## Triple chain-ladder

Parameter estimation

## Parameter estimation procedure

- Applying classical chain-ladder algorithm on three triangles gives estimates of $\vartheta_{i}, \beta_{j}, \pi_{i}, v_{i}, \mu_{j l}$
- Only first moment assumptions are necessary to justify the procedure
- Enough to provide best estimate
- Note also that the model is over-parametrized: authors suggests to put either $\mu_{j l}=\mu_{j}$ or $\mu_{j l}=\mu_{l}$ and, consistently, $s_{j l}=s_{j}$ or $s_{j l}=s_{l}$
- Estimator for the second moment parameters $s_{j l}$ along with further distributional assumptions
- Necessary for the bootstrap
- Rely on the sample estimator

## Triple chain-ladder

Parameter estimation (cont'd)

## From the assumptions, it follows that

- $\mathrm{E}\left[N_{i j}\right]=\vartheta_{i} \beta_{j}$
$\square \mathrm{E}\left[N_{i j}^{\text {paid }}\right]=\vartheta_{i} \lambda_{j}$, where $\lambda_{j}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l}$
$\square \mathrm{E}\left[X_{i j}\right]=\alpha_{i} \gamma_{j}$, where $\alpha_{i}=\vartheta_{i} v_{i}$ and $\gamma_{j}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l} \mu_{j-l, l}$
and
$-\operatorname{Var}\left[N_{i j}\right]=\vartheta_{i} \beta_{j}$
- $\operatorname{Var}\left[N_{i j}^{\text {paid }}\right]=\vartheta_{i} t_{j}^{2}$, where $t_{j}^{2}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l}\left(1+\pi_{l}\right)$
$■ \operatorname{Var}\left[X_{i j}\right]=\alpha_{i} v_{i} \sigma_{j}^{2}$, where $\sigma_{j}^{2}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l} \mu_{j-l, l}\left(\pi_{l} \mu_{j-l, l}+\frac{s_{j-l, l}^{2}}{\mu_{j-l, l}}\right)$

## Thus

- All three random variables - number of claims, number of payments, claim payments - follow (over-dispersed) Poisson model
$\rightarrow$ Ordinary chain-ladder method provides maximum-likelihood estimators of parameters

Ordinary chain-ladder provides by solving system of linear equations (see example for $\mathfrak{\aleph}_{m}$ ) the estimates of:
$\hat{\vartheta}_{i}^{(1)}$ and $\hat{\beta}_{j}$ from triangle $\aleph_{m}$
$\hat{\vartheta}_{i}^{(2)}$ and $\hat{\lambda}_{j}$ from triangle $R_{m}$ $\hat{\alpha}_{i}$ and $\hat{\gamma}_{j}$ from triangle $\Delta_{m}$

$$
\begin{array}{ll}
\sum_{k=0}^{m-i} \mathbb{E}\left[N_{i, k}\right]=\vartheta_{i} \sum_{k=0}^{m-i} \beta_{k} & \text { for } i=1, \ldots, m, \\
\sum_{k=1}^{m-j} \mathbb{E}\left[N_{k, j}\right]=\beta_{j} \sum_{k=1}^{m-j} \vartheta_{k} & \text { for } j=0, \ldots, m-1
\end{array}
$$

Chosen initialization $\vartheta_{1}^{(1)}=\vartheta_{1}^{(2)}=\alpha_{1}=1$ makes solving of the linear system easier. Note that expected values are replaced with observed values. Thus, in the example:

- The first equation for $i=1$ provides the sum $\beta_{0}+\beta_{1}+\ldots+\beta_{m-1}$
- The second equation for $j=m$ - 1 provides solution for $\beta_{m-1}$

■ The first equation then for $i=2$ provides solution for $\vartheta_{2}$, etc.

## There are two estimates of $\vartheta$

- Should not be too different (otherwise it is an indication that the model does not fit)
- It is proposed to use average as the estimate

## Triple chain-ladder

Parameter estimation (cont'd)

From obtained estimates, we can derive estimates of
■ Inflation parameters $v_{i}$ from the equation $\alpha_{i}=\vartheta_{i} v_{i}, i=1, \ldots, m$
■ Payment pattern parameters $\pi_{l}$ from the linear system $\lambda_{j}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l}, j=0, \ldots, m-1$

Due to the above-mentioned over-parametrisation of the model, it is suggested to assume
■ either $\mu_{j l}=\mu_{j}$ - then $\gamma_{j}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l} \mu_{j-l, l}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l} \mu_{j-l}$

- or $\mu_{j l}=\mu_{l}$ - then $\gamma_{j}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l} \mu_{j-l, l}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l} \mu_{l}$

In both cases, the parameters can be estimated again by solving the respective linear system

## Triple chain-ladder

Point forecast of outstanding loss liabilities

## Conditionally expected outstanding loss liability

$$
Z_{m}=\sum_{i=2}^{m} \sum_{j=m-i+1}^{m-1} E\left[X_{i j} \mid \aleph_{m}, R_{m}, \Delta_{m}\right]
$$

Using the model setting, this can be wrriten as

$$
\begin{aligned}
& Z_{m}=\sum_{i=2}^{m} \sum_{j=m-i+1}^{m-1} \sum_{l=0}^{j} E\left[\sum_{k=1}^{N_{i, j l l, l}^{p a i d}} Y_{i, j-l, l}^{(k)} \mid \aleph_{m}, R_{m}, \Delta_{m}\right] \\
& =\sum_{i=2}^{m} \sum_{j=m-i+1}^{m-1} \sum_{l=i+j-m}^{j} E\left[\sum_{k=1}^{\left[N_{i, j-l, l}^{p a i d}\right.} Y_{i, j-l, l}^{(k)} \mid \kappa_{m}, R_{m}, \Delta_{m}\right]+\sum_{i=2}^{m} \sum_{j=m-i+1}^{m-1} \sum_{l=0}^{i+j-m-1} E\left[\sum_{k=1}^{N_{i, j-l, l}^{p a i d}} Y_{i, j-l, l}^{(k)} \mid \aleph_{m}, R_{m}, \Delta_{m}\right]
\end{aligned}
$$

The decoupling is done in a way that

- The first part corresponds to already reported claims (leading to the estimate of RBNS)
- The second part corresponds to not yet reported claims (leading to the estimate of IBNR)

## Triple chain-ladder

Point forecast of outstanding loss liabilities (cont'd)

## Using the model assumptions, we obtain

$$
\begin{aligned}
Z_{m}^{\mathrm{RBNS}} & =\sum_{i=2}^{m} v_{i} \sum_{j=m-i+1}^{m-1} \sum_{l=i+j-m}^{j} N_{i, j-l} \pi_{l} \mu_{j-l, l}, \\
Z_{m}^{\mathrm{IBNR}} & =\sum_{i=2}^{m} \vartheta_{i} v_{i} \sum_{j=m-i+1}^{m-1} \sum_{l=0}^{i+j-m-1} \beta_{j-l} \pi_{l} v_{i} \mu_{j-l, l}
\end{aligned}
$$

Again, the ordinary chain-ladder estimate is obtained if the claim numbers in the "RBNS" part are replaced by $N_{i, j}=\widehat{\vartheta}_{i} \widehat{\beta}_{j}$

■ Unlike for the ordinary chain-ladder, we have a separate estimate for RBNS and IBNR

## Notes

- It feels more natural to use observed values $N_{i j}$ than to replace them as above
- The estimators above do not include the tail. The tail can be estimated similarly to the double chain-ladder. However, the estimate again relies on two assumptions: that no further claims will be reported after $m-1$ periods and (as the whole method) that the payment pattern is not longer than $m-1$ periods.

## Triple chain-ladder

## Case study - best estimate

## Triple chain-ladder

## The bootstrap procedure is analogous to the one for double chain-ladder

- Parametric bootstrap
- Need to specify the distribution of claim payments (gamma chosen in the paper)
- Need to estimate variance parameters in order to estimate the shape and the scale parameter of this distribution

## Estimate of the variance parameters

- To avoid over-parametrisation, it is suggested to put either $s_{j I}=s_{j}$ or $s_{j l}=s_{l}$. We consider the second case here.
- We have $\mathrm{E}\left[X_{i j}\right]=\alpha_{i} \gamma_{j}$ and $\operatorname{Var}\left[X_{i j}\right]=\alpha_{i} v_{i} \sigma_{j}^{2}$ which implies

$$
\mathbb{E}\left[\frac{X_{i, j}-\alpha_{i} \gamma_{j}}{\sqrt{\alpha_{i} v_{i}}}\right]=0 \quad \text { and } \quad \operatorname{Var}\left(\frac{X_{i, j}-\alpha_{i} \gamma_{j}}{\sqrt{\alpha_{i} v_{i}}}\right)=\sigma_{j}^{2}
$$

- The sampler estimator then provides for $j=0, \ldots, m$-2 (it is suggested to put $\hat{\sigma}_{m-1}^{2}=\hat{\sigma}_{m-2}^{2}$ )

$$
\widehat{\sigma}_{j}^{2}=\frac{1}{m-j-1} \sum_{i=1}^{m-j}\left(\frac{X_{i, j}-\widehat{\alpha}_{i} \widehat{\gamma}_{j}}{\sqrt{\widehat{\alpha}_{i} \widehat{v}_{i}}}\right)
$$

■ The formula $\sigma_{j}^{2}=\sum_{l=0}^{j} \beta_{j-l} \pi_{l} \mu_{j-l, l}\left(\pi_{l} \mu_{j-l, l}+\frac{s_{j-l, l}^{2}}{\mu_{j-l, l}}\right)=\sum_{l=0}^{j} \beta_{j-l} \pi_{l} \mu_{l}\left(\pi_{l} \mu_{l}+\frac{s_{l}^{2}}{\mu_{l}}\right)$ determines then a linear system for $s_{l}^{2}$

- It is suggested to check coefficients of variation $\widehat{\mathrm{vCo}}=\hat{s}_{l} / \hat{\mu}_{l}$ for their plausibility

## Proposed algorithm for the bootstrapping procedure - RBNS part

Estimate of process variance only - do only steps 1,4 and 5 (using parameters estimated in the step 1).

## 1. Parameters estimation

- Apply the triple chain-ladder procedure to estimate all model parameters $\left(Y_{i j l} \sim \Gamma\left(\hat{\lambda}=\frac{\widehat{\mu}_{l}^{2}}{\hat{s}_{l}^{2}-\widehat{\mu}_{l}^{2}}, \hat{\kappa}=\frac{\left(\hat{s}_{l}^{2}-\widehat{-}_{l}^{2}\right) \hat{v}_{j}}{\widehat{\mu}_{l}}\right)\right)$

2. Bootstrapping the data

- Keep the same counts $N$, but bootstrap the aggregate number of payments $\mathrm{R}^{*}$ and payments $\mathrm{X}^{*}$ as follows
- Simulate the payment delay: $N_{i j}$ paid ${ }^{*} \sim \operatorname{Poi}\left(N_{i j} \hat{\pi}_{l}\right)$ with $\hat{\pi}_{l}$ estimated in the step 1
- Simulate the aggregate payments $X_{i j}{ }^{*}$ using simulated $N_{i j}{ }^{\text {paid }}$ and gamma distribution estimated in the step 1

3. Bootstrapping the parameters

- From the bootstrap data ( $N, R^{*}, X^{*}$ ) generated at step 2 obtain new estimates for parameters

4. Bootstrapping the RBNS prediction

- Simulate the delay as in the step 2
- Simulate the aggregate payments as in the step 2
- Get the bootstrapped RBNS prediction

5. Monte Carlo approximation

- Repeat steps 2-4 B times and get the empirical bootstrap distribution of the RBNS part of the reserve

## Triple chain-ladder

Bootstrap (cont'd) and case study in the paper

## Proposed algorithm for the bootstrapping procedure - IBNR part

- Analogous to RBNS part
- Steps 2-4 include the estimation and the simulation of the number of reported claims in the lower triangle
- Number of reported claims are simulated from the Poisson distribution with means $\hat{\vartheta}_{i} \hat{\beta}_{j}$

## Case study

- Higher uncertainty compared to DCL
- The advantage of DCL (less parameters) is not outweighted by the more detailed modeling in TCL

|  | TCL |  |  | RBNS | IBNR | total |
| :---: | ---: | ---: | ---: | ---: | ---: | ---: |

cutting through complexity

## Summary

## Double-chain ladder

- Use primarily information from two triangles: claims counts and paid
- Two formulations for best estimate
- First moment (distribution-free)
- Parametric
- Can replicate classical chain-ladder results
- with a split of the RBNS and IBNR cash-flows
- Provides an alternative estimate which is more natural to the underlying assumptions
- Parametric bootstrapping can be used for an assessment of the full distribution
- Alternative to the bootstrapping procedures common for classical chain-ladder
- Allows for several extensions (BDCL, Triple chain-ladder)
- Prior knowledge can be incorporated in the assessment of best estimate and in the bootstrap procedure
- Zero claims
- Future claims development inflation

Implementation of DCL and BDCL in R is publicly available

## Appendix A

## Claims amounts follow ODP model

## Mean

$$
\begin{aligned}
E\left[X_{i j} \mid \aleph_{m}\right] & =E\left[E\left[X_{i j} \mid N_{i j}^{\text {paid }}\right] \mid \aleph_{m}\right] \\
& =E\left[E\left[\sum_{k=1}^{N_{i j}^{\text {paid }}} Y_{i j}^{(k)} \mid N_{i j}^{\text {paid }}\right] \mid \aleph_{m}\right] \\
& =E\left[N_{i j}^{\text {paid }} E\left[Y_{i j}^{(k)}\right] \mid \aleph_{m}\right] \\
& =E\left[N_{i j}^{\text {paid }} \mid \aleph_{m}\right] E\left[Y_{i j}^{(k)}\right]
\end{aligned}
$$

## Variance

$$
\begin{aligned}
V\left[X_{i j} \mid \aleph_{m}\right] & =E\left[V\left[X_{i j} \mid N_{i j}^{p a i d}\right] \mid \aleph_{m}\right]+V\left[E\left[X_{i j} \mid N_{i j}^{\text {paid }}\right] \mid \aleph_{m}\right] \\
& =E\left[V\left[\sum_{k=1}^{N_{i j}^{p a i d}} Y_{i j}^{(k)} \mid N_{i j}^{p a i d}\right] \mid \aleph_{m}\right]+V\left[N_{i j}^{p a i d} E\left[Y_{i j}^{(k)}\right] \mid \aleph_{m}\right] \\
& =E\left[N_{i j}^{p a i d} V\left[Y_{i j}^{(k)}\right] \mid \aleph_{m}\right]+V\left[N_{i j}^{p a i d} E\left[Y_{i j}^{(k)}\right] \mid \aleph_{m}\right]
\end{aligned}
$$

## Appendix A

Claims amounts follow ODP model (cont'd)

Since we assume (without any loss of generality, we omit indeces i)

$$
\mathrm{E}\left[Y_{i j}(k)\right]=\mu, \quad \mathrm{V}\left[Y_{i j}(k)\right]=\sigma^{2}
$$

Thus

$$
\begin{aligned}
& E\left[X_{i j} \mid \aleph_{m}\right]=E\left[N_{i j}^{\text {paid }} \mid \aleph_{m}\right] \mu \\
& V\left[X_{i j} \mid \aleph_{m}\right]=E\left[N_{i j}^{\text {paid }} \mid \aleph_{m}\right] \sigma^{2}+V\left[N_{i j}^{\text {paid }} \mid \aleph_{m}\right] \mu^{2}
\end{aligned}
$$

Using the assumption of conditional multinomial distribution of $N_{i j}^{\text {paid }}$

$$
\begin{aligned}
E\left[N_{i j}^{\text {paid }} \mid \aleph_{m}\right] & =E\left[\sum_{k=0}^{\min \{j, d\}} N_{i, j-k, k}^{\text {paid }} \mid \aleph_{m}\right] \\
& =\sum_{k=0}^{\min \{j, d\}} E\left[N_{i, j-k, k}^{\text {paid }} \mid \aleph_{m}\right] \\
& =\sum_{k=0}^{\min \{j, d\}} N_{i, j-k} p_{k}
\end{aligned}
$$

Appendix A
Claims amounts follow ODP model (cont'd)

Assuming that the numbers of claims paid from different origin years are uncorrelated

$$
\begin{aligned}
V\left[N_{i j}^{\text {paid }} \mid \aleph_{m}\right] & =V\left[\sum_{k=0}^{\min \{j, d\}} N_{i, j-k, k}^{\text {paid }} \mid \aleph_{m}\right] \\
& =\sum_{k=0}^{\min \{j, d\}} V\left[N_{i, j-k, k}^{\text {paid }} \mid \aleph_{m}\right] \\
& =\sum_{k=0}^{\min \{j, d\}} N_{i, j-k} p_{k}\left(1-p_{k}\right)
\end{aligned}
$$

## Appendix A

Claims amounts follow ODP model (cont'd)

## Hence

$$
\begin{aligned}
E\left[X_{i j} \mid \aleph_{m}\right] & =\sum_{k=0}^{\min \{j, d\}} N_{i, j-k} p_{k} \mu \\
V\left[X_{i j} \mid \aleph_{m}\right] & =\sum_{k=0}^{\min \{j, d\}} N_{i, j-k} p_{k} \sigma^{2}+\sum_{k=0}^{\min \{j, d\}} N_{i, j-k} p_{k}\left(1-p_{k}\right) \mu^{2} \\
& =\sum_{k=0}^{\min (j, d)} N_{i, j-k}\left\{\sigma^{2} p_{k}+\mu^{2} p_{k}\left(1-p_{k}\right)\right\} \\
& \approx \sum_{k=0}^{\min \{j, d\}} N_{i, j-k} p_{k}\left(\sigma^{2}+\mu^{2}\right)
\end{aligned}
$$

Last approximation is done so that the variance is proportional to the mean
$\rightarrow$ An over-dispersed Poisson model may be used.
